Recall termination in free recall

**Jonathan F. Miller · Christoph T. Weidemann ·
Michael J. Kahana**

Abstract Although much is known about the dynamics of
memory search in the free recall task, relatively little is
known about the factors related to recall termination. Rean-
alyzing individual trial data from 14 prior studies (1,079
participants in 28,015 trials) and defining termination as
occurring when a final response is followed by a long
nonresponse interval, we observed that termination proba-
bility increased throughout the recall period and that retriev-
al was more likely to terminate following an error than
following a correct response. Among errors, termination
probability was higher following prior-list intrusions and
repetitions than following extralist intrusions. To verify that
this pattern of results can be seen in a single study, we report
a new experiment in which 80 participants contributed recall
data from a total of 9,122 trials. This experiment replicated
the pattern observed in the aggregate analysis of the prior
studies.

Keywords Memory · Recall

We are commonly faced with the situation of trying to recall
a set of items learned in a given context, without regard to
the order in which the items were experienced. In the labo-
ratory, this type of memory is studied using the free recall

task; after studying a list of items (typically words), partic-
ipants are asked to recall the list items in any order. The
unconstrained nature of the free recall task provides a rich
source of information on the nature of the retrieval cues used
during memory search. The analysis of the dynamics of free
recall has revealed the importance of semantic relatedness
and temporal contiguity in guiding recall (e.g., Howard &
Kahana, 2002; Kahana, 1996). Such analyses have also
played an important role in developing and testing theories
of memory retrieval (e.g., Davelaar, Goshen-Gottstein,
Ashkenazi, Haarmann, & Usher, 2005; Kimball, Smith, &
Kahana, 2007; Laming, 2010; Polyn, Norman, & Kahana,
2009; Sederberg, Howard, & Kahana, 2008).

Although much attention has been paid to the way people
make transitions from one response to the next, two other
components of the recall process are also of critical impor-
tance: recall initiation and recall termination. Recall initia-
tion was a major focus of Deese and Kaufman's (1957)
classic study of the serial position effect in free recall. They
documented the relation between the recency effect (supe-
rior recall of end of list items) and participants' tendency to
initiate recall with items from the end of the list. Subsequent
analyses of recall initiation have enriched our understanding
of the recency effect in both immediate free recall and free
recall following various distractor schedules (Bhatarah,
Ward, & Tan, 2008; Davelaar et al., 2005; Laming, 1999,
2010; Sederberg et al., 2008).

Much less, however, is known about the factors respon-
sible for recall termination. In a study of interresponse times
(IRTs) in free recall, Murdock and Okada (1970) found that
the IRT prior to the final correct response tended to be
approximately 8–10 s, regardless of how many items the
participant recalled. They also showed that IRTs increased
exponentially with output position (i.e., the position of a
response in the sequence of recalls; see also Polyn et al.,

2009; Wixted & Rohrer, 1994). This suggests that participants may terminate recall following a long period in which no new items are successfully retrieved.

Whereas Murdock and Okada (1970) inferred recall termination on the basis of the final correct response given in a fixed recall period, in a more recent study, Dougherty and Harbison (2007) assessed recall termination by asking participants to press a key when they could not remember any additional items. Dougherty and Harbison found that the duration between the last successful retrieval and the termination response (exit latency) decreased as the total number of items recalled increased. Furthermore, the researchers showed that variability in exit latencies was closely related to participants' decisiveness, with participants who scored high on a decisiveness scale terminating recall more quickly.

An important feature of the recall process not considered in these previous studies concerns the nature of the responses themselves. Although most recalled items are correct responses (i.e., items studied on the target list), participants also occasionally commit errors by recalling items studied on an earlier list but not on the current list (prior-list intrusions), recalling items not studied on the current list or any earlier list (extralist intrusions), or repeating already recalled items. It is known that errors tend to occur late in recall (Kimball et al., 2007; Roediger & McDermott, 1995) and that they elicit subsequent errors (Zaromb et al., 2006). As such, one might hypothesize that whatever process contributes to recall errors may also play a role in recall termination. To test this hypothesis, we asked whether the conditional probability of stopping differed following various types of recall events. Because these events occur with different frequencies during the recall process, we compute these conditional probabilities separately as a function of output position. For this purpose, we have carried out secondary analyses of the raw trial-by-trial data culled from 1,079 participants across 14 large free recall experiments, comprising a total of 28,015 recall trials (for a description of each experiment, see the Appendix). By pooling raw data from so many trials, we were able to look at relatively rare events that happen during recall and to see how these events predicted recall termination. To foreshadow our results, we found that retrieval is more likely to terminate following recall errors than following correct responses, and that this effect appears consistently throughout the recall period. The increased tendency to terminate recall after committing an error varied significantly across the three types of recall errors that we studied: prior-list intrusions, extralist intrusions, and repetitions. After reanalyzing these prior data sets, we further validated our results by showing that the same pattern of increased termination following errors can be seen in a single new experiment, reported below.

Meta-analysis methods

We reanalyzed individual-trial data from the 14 experiments listed in Table 1. Our criteria for inclusion was stringent. First, we limited our secondary analysis to studies for which we could obtain individual-trial data for each participant. Second, we required those data to include information on the order of individual responses on each trial, including errors. Third, we excluded studies for which the nature of the recall errors was not classified according to the three key categories: prior-list intrusions, extralist intrusions, and repetitions. Finally, we further limited our analyses to studies reporting the timing of individual responses. Nonetheless, we were able to include data from 10 experimental conditions reported in seven published articles, and an additional 4 studies reported in working papers. In each of the included studies, the lists consisted of between 10 and 25 common words (often nouns selected from the Toronto Word Pool; see Friendly, Franklin, Hoffman, & Rubin, 1982) and recall was vocal, with speech being digitized and latencies recorded. The appendix provides brief descriptions of the methods used in each of the experiments we analyzed.

In free recall tasks, participants are typically given a fixed amount of time to recall the list items. As such, these studies do not tell us when recall actually terminates. For example, one may ask whether the recall period has terminated while the participant is still actively recalling words, whether the participant has given up early in the recall interval, or whether the participant is trying hard to recall items, but nothing is coming to mind. Another possibility is that recall terminates because participants have already recalled all of the list items. However, the latter situation almost never happens with the long lists used in these (and most) free recall studies. What we do know, on the basis of recall latencies, is that participants make most of their responses early in the recall period and that the time between successive recalls increases approximately exponentially with output position (Murdock & Okada, 1970; Polyn et al., 2009; Rohrer & Wixted, 1994).

In the present study, we define recall termination as occurring when the time between the last recalled item and the end of the fixed recall period was both longer than every IRT on the current trial and exceeded a criterion of 12 s. This value was chosen to exceed the mean exit latency of 10 s reported by Dougherty and Harbison (2007) in an open-ended retrieval period. Out of 28,015 trials, 18,829 met these criteria (67.21%). In the included trials, there were a total of 127,240 responses: 111,211 (87.40%) were correct, 3,589 (2.82%) were repetitions, 6,000 (4.72%) were prior-list intrusions, and 6,440 (5.06%) were extralist intrusions. Of the prior-list intrusions, 41% had been correctly recalled on their initial presentation list. We repeated our analyses without excluding any trials and obtained nearly identical results.

Table 1 Summary of experimental conditions

Study	N	LL	PR (s)	Dist. (s)	RP (s)

N indicates sample size, LL indicates list length, PR indicates presentation rate (in seconds), Dist. indicates duration of an end-of-list arithmetic distractor task (in seconds; 0 indicates *no distractor*), and RP indicates recall period duration (in seconds)

Meta-analysis results

Figure 1A shows the conditional probabilities of recall termination following correct responses and each type of recall error, as a function of output position (for the first eight output positions during recall).[1] We defined recall errors as repetitions of an already recalled item, as prior-list intrusions (PLIs), or as extralist intrusions (ELIs). We determined each participants' probability of recall termination by dividing, separately for each output position and response type, the number of responses that were the final response in a trial by the total number of responses of that type. When calculating the mean probabilities for each response type and output position, the participants' data were weighted according to the number of responses they contributed. To assess differences in the probability of recall termination following the four response types, we calculated bias-corrected and accelerated bootstrap 95% (two-tailed) confidence intervals (Efron & Tibshirani, 1993) for all six possible differences at each output position (see Fig. 1B). We considered differences with confidence intervals that did not include zero to be significant.

Across the first eight output positions, which subsume the majority of the recall data across these experiments, participants were more likely to terminate recall following PLIs than following either ELIs or correct responses. For the later output positions (5–8), participants were also very likely to terminate recall following repetitions: The termination probabilities were similar following either repetitions or PLIs and exceeded the probabilities following both ELIs and correct responses. Recall termination rates following ELIs were generally intermediate between the rates for PLIs and correct responses. Recall termination was significantly more likely to occur following ELIs than following correct responses (for Output Positions 3–8) and significantly less likely than recall termination following PLIs (at all output positions) or repetitions (Output Positions 5–8). The pattern of results seen in the figure is thus quite reliable in our large sample of data: People are more likely to terminate recall following errors than following correct responses, and among the errors, recall termination is generally higher following PLIs and repetitions than following ELIs. One exception is the significantly lower probability of terminating recall following repetitions than following PLIs at Output Positions 3 and 4.

To further evaluate these results, we determined for each participant the earliest output position after which recall stopped, and then we aggregated the corresponding probabilities for the different response types across participants (e.g., if one participant always recalled at least four items and another always recalled at least six items, we aggregated the probabilities for Output Positions 4 and 6 for these participants). We aligned output positions at both the individually determined first and last stopping positions, and in both cases, we observed
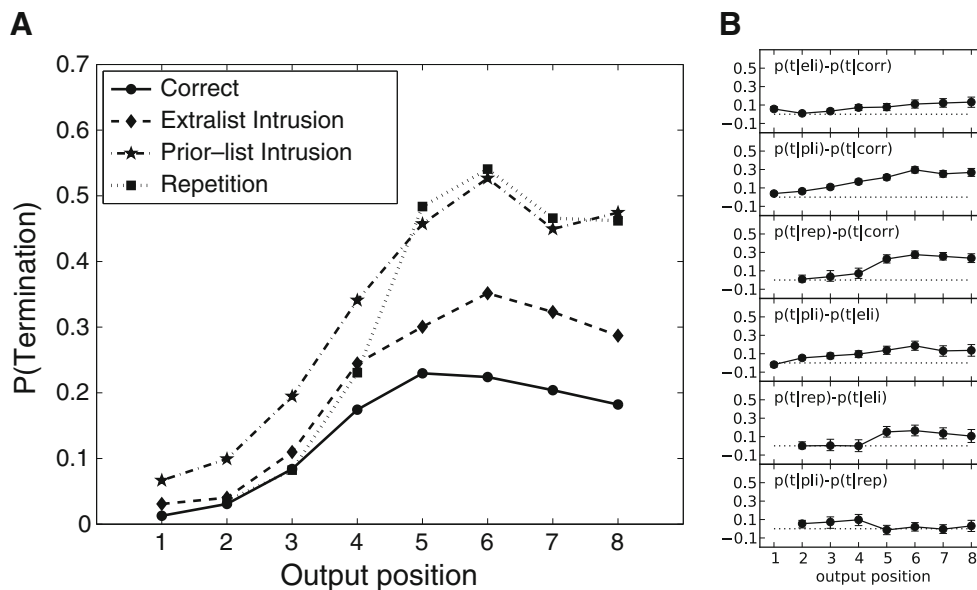

---

[1] Because these analyses were conducted across a wide range of experiments, which varied in list length and other parameters, we had to restrict our analyses to a fixed number of output positions that would subsume the majority of the recall data across these studies (in this case, the first eight recalled items). Although participants occasionally recalled more than eight items, especially in experiments involving longer lists and slower presentation rates, it would be very difficult to show those data in these aggregate analyses. In Experiment 1, described below, we provide data on later output positions in a study involving lists of 16 items.

Fig. 1 Recall termination following errors and correct responses. (A) Termination probabilities following correct recall, extralist intrusions, prior-list intrusions, and repetitions: Aggregate data from 14 free recall experiments. (B) Differences in the probabilities of termination, $p(t)$, between the various response types (designated "corr," "eli," "pli," and "rep," for correct, extra-list intrusion, prior-list intrusion, and repetition, respectively), along with the corresponding 95% (two-tailed) confidence intervals (determined by bias-corrected and accelerated nonparametric bootstrap: Efron & Tibshirani, 1993). The dashed lines indicate zero difference

an ordering of probabilities of stopping that was consistent with that shown in Fig. 1: Probabilities of stopping tended to be lowest following correct recalls, greater after ELIs, and even greater after PLIs and repetitions. Repeating all of the above analyses without excluding any trials on the basis of our recall termination criteria yielded virtually identical results.

Although the results of the meta-analysis seem clear, some readers might not be at ease with analyses aggregated across so many diverse data sets. We therefore sought to validate these results in a single, large experiment. Fortuitously, at the time of this writing we were in the midst of conducting a large-scale study on the electrophysiological correlates of memory encoding and retrieval in free recall (Long, Miller, Sederberg, & Kahana, 2011). With 80 participants having completed seven experimental sessions, each involving free recall of 16 study–test lists, we had sufficient power to assess whether the patterns observed in the meta-analysis would replicate in a single study.

Experiment

Method

Participants A group of 80 participants performed a free recall experiment consisting of one practice session and six subsequent experimental sessions. The participants provided informed consent according the University of Pennsylvania's Institutional Review Board protocol and were compensated for their participation. Each session lasted approximately 1.5 h.

Procedure Each session consisted of 16 lists of 16 words presented one at a time on a computer screen. Each study list was followed by an immediate free recall test, and each session ended with a recognition test. Half of the sessions (randomly chosen) included a final free recall test before recognition, in which participants recalled words from any of the lists from the session. This experiment was part of a larger study that included electroencephalogram recordings and further manipulations of the recognition and recall periods (Long et al., 2011).

Items were presented either with a task cue, indicating what judgement the participant should make about the word, or were associated with no encoding task. The two encoding tasks were a size judgment ("Will this item fit into a shoebox?") and an animacy judgment ("Does this word refer to something living or not living?"), and the current task was indicated by the color and typeface of the presented item. There were three conditions: control lists (no task), task lists (all items were presented with the same task), and task shift lists (individual items were presented with either task). List and task order were counterbalanced across both sessions and participants. Additionally, using the results of a prior norming study, only words that were clear in meaning and that could be reliably judged in the size and animacy encoding tasks were included in the pool.

Each word was drawn from a pool of 1,638 words. The lists were constructed such that varying degrees of semantic relatedness occurred at both adjacent and distant serial positions. Semantic relatedness was determined using the word association space (WAS) model described by Steyvers, Shiffrin, and Nelson (2004). WAS similarity values were used to group

words into four similarity bins (high similarity, cos θ between words > 0.7; medium-high similarity, $0.4 < \cos \theta < 0.7$; medium-low similarity, $0.14 < \cos \theta < 0.4$; and low similarity, $\cos \theta < 0.14$). Two pairs of items from each of the four groups were arranged such that one pair occurred at adjacent serial positions and the other pair was separated by at least two other items.

Each item was on the screen for 3,000 ms, followed by a jittered 800- to 1,200-ms interstimulus interval (uniform distribution). If the word was associated with a task, participants indicated their response via a keypress. After the last item in the list, there was a 1,200- to 1,400-ms jittered delay, after which a tone sounded, a row of asterisks appeared, and the participant was given 75 s to attempt to recall any of the just-presented items.

Results

Before reporting on recall termination following various types of errors, we will first show the results of more standard analyses applied to this data set. Standard serial position effects were observed, with marked recency, as would be expected in any immediate free recall task, and a moderately strong primacy effect extending about four or five serial positions into the list (Fig. 2A). Related to the recency effect, participants exhibited a strong tendency to begin recall with one of the last few items—a tendency that slowly dissipated across subsequent recalls (Fig. 2B).

The dynamics of free recall are largely characterized by the contiguity (or lag recency) effect and by the semantic proximity effect: That is, recall of an item tends to be followed by recall of a neighboring or similar item. The contiguity effect in this experiment, as shown in Fig. 2C, showed the usual forward asymmetry (Kahana, 1996). The semantic proximity effect in this experiment, shown in Fig. 2D, was similar whether semantic relatedness was defined by WAS similarity or latent semantic analysis (Landauer & Dumais, 1997). Because the results described above were only minimally affected by the different encoding conditions, we report all analyses collapsed across these conditions.

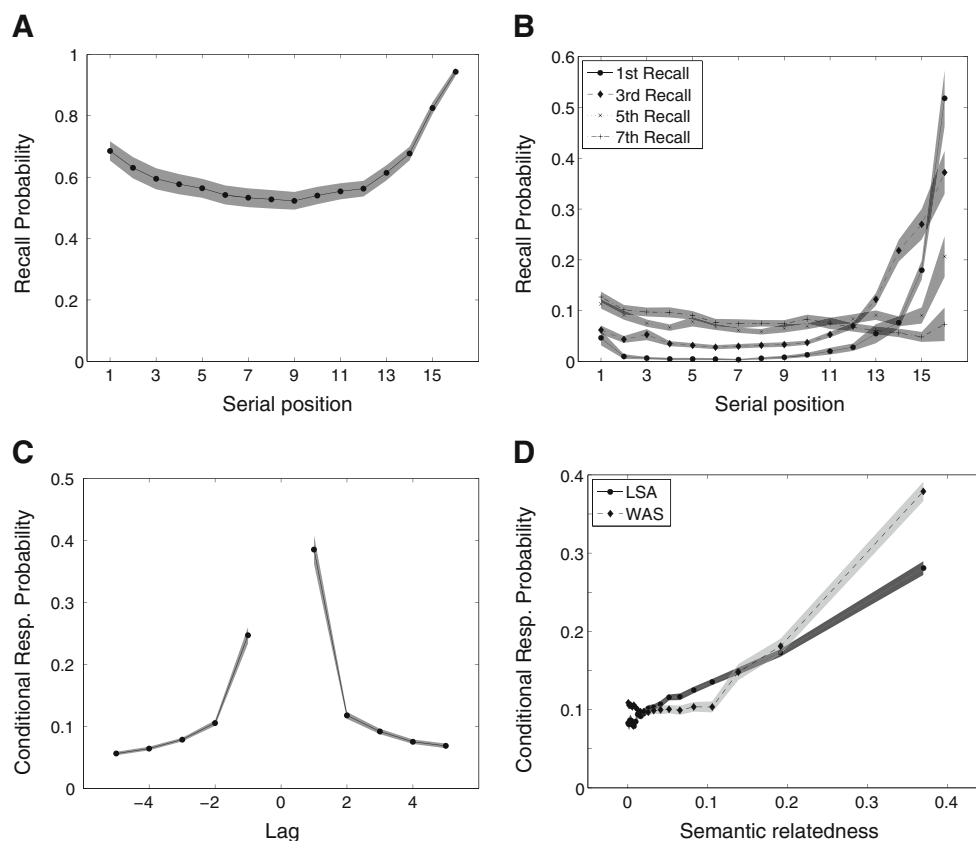

Fig. 2 Serial position, temporal contiguity, and semantic proximity effects for the data from the reported experiment. The shaded regions are 95% confidence intervals. (A) Recall probability as a function of serial position. (B) Recall probability as a joint function of serial position and output position, conditional on participants having made a response at a given output position. Serial position curves are shown for output positions 1, 3, 5, and 7. The serial position curve for output position 1 is frequently referred to as the first recall probability. (C) The lag conditional response probability (lag-CRP) function shows the conditional probabilities of recalling items presented in serial position i + lag, where i is the serial position of the just-recalled item. (D) The semantic conditional response probability (semantic-CRP) function shows the conditional probabilities of recalling items from a given level of semantic relatedness as determined using latent semantic analysis (LSA) or word association spaces (WAS). See text for details

Recall termination effects were analyzed in the same manner as in the meta-analyses described above. Because there were very few trials with fewer than 4 correct responses (3.7%) or more than 12 correct responses (26%), we limited our analyses to Output Positions 4–12. Of the 9,122 trials, 6,527 met our inclusion criteria for selecting trials in which participants were likely to have terminated recall. The included trials comprised a total of 67,671 responses: 64,348 (95.09%) were correct, 1,570 (2.32%) were repetitions, 563 (0.83%) were prior-list intrusions, and 1,190 (1.76%) were extralist intrusions.

As is shown in Fig. 3A, the tendency to terminate recall was greater following PLIs, ELIs, and repetitions than following correct responses. Furthermore, the ordering of the termination probabilities was identical to that in the aggregate analyses—being highest following PLIs, next highest following repeti-

tions, lower following ELIs, and lowest following correct responses. With the exception of the comparison between ELIs and correct responses, each of the other comparisons was statistically significant in the predicted direction for a majority of output positions between Positions 4 and 12 (see Fig. 3C). Additionally, we performed the previously described aligned output position analysis on these data and observed an ordering of probabilities matching those shown in Fig. 3A. We also repeated the analyses without excluding any trials. As is shown in Figs. 3B and 3D, these results were nearly identical to those based on our trial exclusion criteria.

A somewhat unusual feature of the present study, and also of several studies in the meta-analysis described above, was the high level of experience that participants obtained with the free recall task. One may therefore wonder whether these results reflect strategies that developed through extensive

Fig. 3 Recall termination following errors and correct responses. (A) Termination probabilities following correct recall, extralist intrusions, prior-list intrusions, and repetitions: Data from the reported experiment. (B) Termination probabilities following correct recall, extralist intrusions, prior-list intrusions, and repetitions: Data from the reported experiment with no trials excluded. (C and D) Differences in probabilities of termination, p(t), between the various response types (designated "corr," "eli," "pli," and "rep," for correct, extra-list intrusion, prior-list intrusion, and repetition, respectively) along with the corresponding 95% (two-tailed) confidence intervals (determined by bias-corrected and accelerated non-parametric bootstrap: Efron & Tibshirani, 1993). The dashed lines indicate zero difference. Panel C corresponds to data from panel A, and panel D corresponds to data from panel B
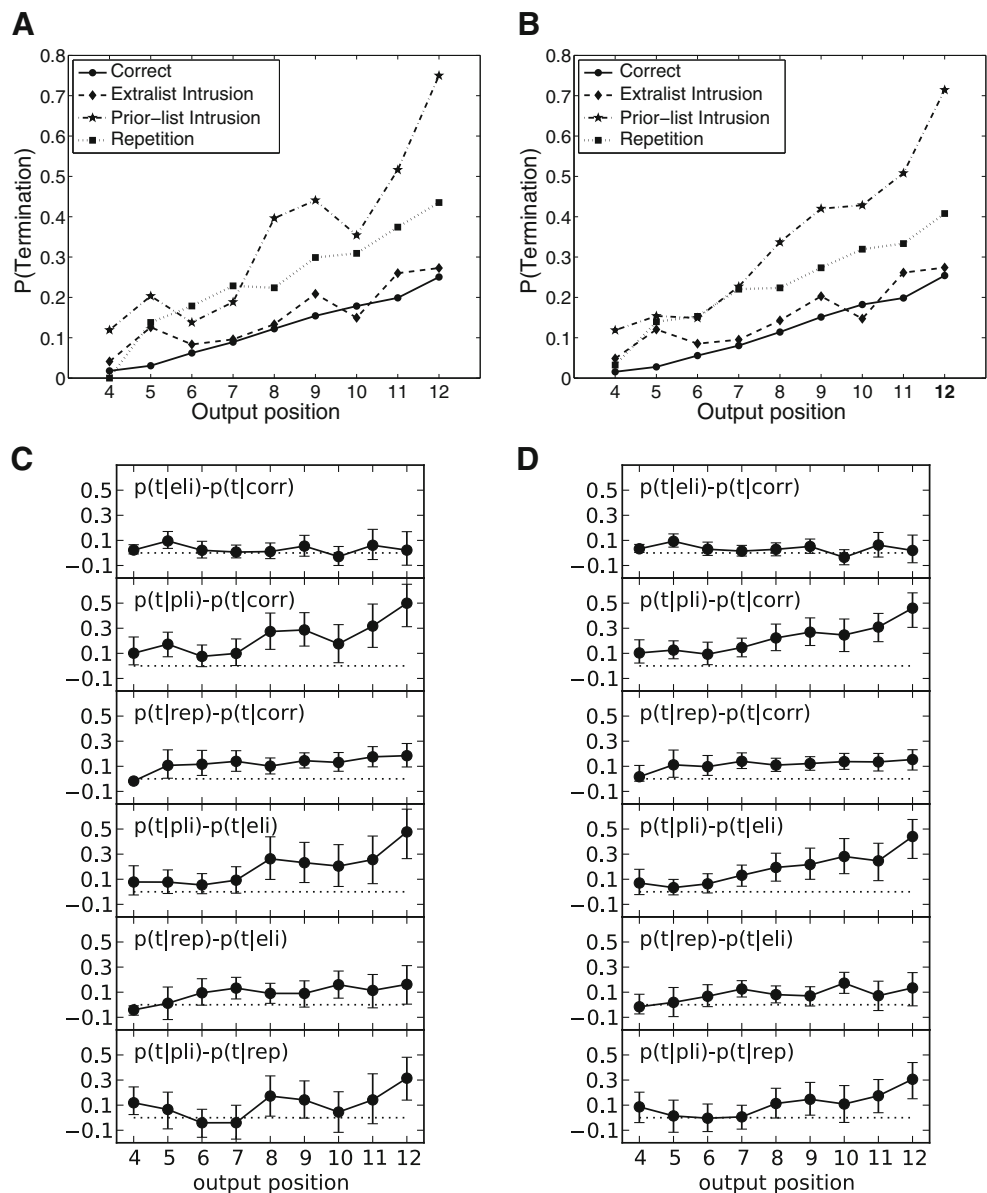

practice, or whether they are typical of the results that would be obtained with less highly practiced participants. We addressed this question by separately analyzing data from the first and last sessions of the reported experiment (Sessions 1 and 7). As is shown in Fig. 4, recall termination was more likely after incorrect than after correct responses for both the first and last sessions. Additional analyses revealed that the order of the probabilities for correct responses, ELIs, repetitions, and PLIs matched those shown in Figs. 1 and 3 for both Sessions 1 and 7.

Discussion

Understanding recall termination is particularly important because whatever accounts for recall termination determines the total number of items that are ultimately recalled. Although previous research has revealed a great deal about how people initiate recall and how they transition between successively recalled items, much less is known about the correlates of recall termination.

Through a reanalysis of individual-trial data from 14 experiments in previous studies, as well as from a newly reported study, we found that termination is consistently more likely to occur after an error than after a correct recall, and that this tendency to terminate recall following an error depends on the kind of error that is made. Recall termination is most likely to follow prior-list intrusions and repetitions of already recalled items, less likely to follow extralist intrusions, and least likely to follow correct responses.

Models of free recall in which retrieval of an item serves as a cue for the next response (e.g., Howard, Kahana, & Wingfield, 2006; Kimball et al., 2007; Metcalfe & Murdock,

Fig. 4 Termination probabilities following correct recall and incorrect responses. The data are from the first session (S1; filled circles) and the last session (S7; open squares) of the experiment

1981; Polyn et al., 2009; Raaijmakers & Shiffrin, 1980; Sederberg et al., 2008) have suggested that the increased tendency to terminate recall following errors may reflect a fundamental memory process. Specifically, these models assume that neighboring items are associated during study, and that recall of an item tends to also retrieve items studied in proximate list positions. In this way, the models account for the well-known contiguity effect, which is seen in people's strong tendency to successively recall items studied in neighboring list positions (Kahana, 1996). By the same logic, these models predict that intrusions will tend to be poor cues for subsequent correct recalls. For example, the recall of an item presented on an earlier list is likely to be a good cue for other items from the prior list, which compete with items from the current list. Zaromb et al. (2006) provided empirical support for this proposition. They found that participants were significantly more likely to commit PLIs following other PLIs, and further, that such intrusions tended to come from the same prior list. Zaromb et al. also found that when an item on the current list had been presented on an earlier list, recall of that item was more frequently followed by a PLI than by recall of a current-list item. Thus, PLIs tend to retrieve contextual information that is inappropriate to the current list, and therefore lead to further recall errors and recall termination. By the same logic, ELIs are also poor recall cues. Although such responses do not evoke specific competition from recently studied items, they are nonetheless poor retrieval cues, insofar as their associated temporal context will not serve as an effective cue for current-list items.

To the extent that the specific competition from recent (prior) list responses is greater than the competition associated with extralist associations (as discussed above), one would expect the probability of termination to be greater following PLIs than following ELIs, as we have observed. It is somewhat less obvious, however, why participants would be nearly as likely to terminate recall following repetitions as following PLIs. Such items do not harbor strong associations to items on earlier lists and are not strongly associated with temporal contexts that are unrelated to other list items. On the other hand, the fact that repetitions had previously been recalled suggests that the list items that were effective at cuing these repeated items were likely to have already been recalled as well. This account also suggests an explanation for the lower probability of terminating recall following repetitions at early output positions, when only few items have been recalled, since it is likely that items cued by the repeated item are still available for recall, and thus the detrimental effects of repetitions should be limited to later output positions. One might expect that repeating an already recalled item at later output positions would activate other recalled items, which would simply consume retrieval time without leading to another correct response (and thereby
leading to increased termination probabilities). The idea that resampling and rejecting previously recalled items consumes retrieval time, and thus predicts recall termination in a fixed-interval task, forms the basis of accounts of the exponential growth of IRTs in free recall (Murdock & Okada, 1970; Rohrer & Wixted, 1994).

The finding that people are more likely to terminate recall following errors than following correct responses, even when controlling for output positions and recall time, adds to a growing body of evidence that recall of an item evokes contextual information previously associated with that item and that this contextual information can serve to either support or hinder subsequent recall (for a review, see Kahana, Howard, & Polyn, 2008). Whereas earlier evidence for this process was based solely on recall transitions, the present study suggests that recall termination depends on the loss of appropriate retrieval cues.

Although the observed pattern of results suggests a causal relation between recall errors and recall termination, one cannot strictly rule out the possibility that these results arise from some other endogenous aspect of the recall process that gives rise to both recall error and recall termination. Future research will be able to better adjudicate between these theoretical accounts by testing sophisticated process models of recall that can simultaneously fit data on recall initiation, recall transitions, and recall termination. The serious consideration of recall termination data in these models will in turn enable the models to speak more clearly to the memory mechanisms that underlie recall impairments in both healthy aging and neurological disease (see, e.g., Dubois & Albert, 2004; Golomb, Peelle, Addis, Kahana, & Wingfield, 2008; Grober, Lipton, Hall, & Crystal, 2000; Kahana, Howard, Zaromb, & Wingfield, 2002).

Appendix: Details of the included experiments

Howard and Kahana (1999), Exp. 1 In single sessions, 62 participants (1 was excluded from the original study because of experimenter error) performed both immediate and delayed free recall of 25 total lists. The first 2 lists for each participant were treated as practice, while the remaining 23 lists were randomly selected for either immediate or delayed free recall (i.e., participants performed different numbers of delayed free recall lists, ranging from 4 to 16 total lists). Each list was composed of 12 randomly selected nouns from the Toronto Word Pool (Friendly et al., 1982). The words

were presented visually for 1,000 ms each. While each word was on the screen, participants were required to perform a semantic orienting task, judging whether each word was "concrete" or "abstract" by pressing either the left or the right control key. After the presentation of the last item, participants either immediately began recall or performed true/false math problems of the form $A + B + C = D$ (where A, B, and C were positive, single-digit integers) for 10 s. Participants recalled the words on the just-studied list in any order during a 45-s recall period.

Howard and Kahana (1999), Exp. 2 Over the course of 10 sessions, 16 participants performed four variants of free recall (one delayed and three continual-distractor variants, with varying durations of a distractor-filled interstimulus interval [ISI]). Each list was composed of 12 nouns selected at random and without replacement from the Toronto Word Pool (Friendly et al., 1982). The words were presented visually for 1,200 ms each. While each word was on the screen, participants were required to perform a semantic orienting task, judging whether each word was "concrete" or "abstract" by pressing either the left or the right control key. After presentation of the last item, participants performed true/false math problems of the form $A + B + C = D$ (where A, B, and C were positive, single-digit integers) for 16 s. Then participants recalled the words on the just-studied list in any order during a 60-s recall period.

Kahana et al. (2002), Exp. 1 In single sessions, 28 older and 31 younger participants performed immediate free recall of 33 lists. The 10 words in each list were presented visually for 1,400 ms, followed by a 100-ms ISI. Immediately following the presentation of the last item, participants began recalling the words on the just-studied list in any order during a 45-s recall period.

Kahana et al. (2002), Exp. 2 In single sessions, 25 older and 25 younger participants performed delayed free recall of 23 lists. The 10 words in each list were presented visually for 1,400 ms, followed by a 100-ms ISI. After the presentation of the last item, participants solved math problems of the form $A + B + C = ?$ (where A, B, and C were positive, single-digit integers) for 16 s before recalling the words on the just-studied list in any order during a 45-s recall period.

Kahana and Howard (2005), Massed lists A group of 65 participants performed delayed free recall of word lists with either massed or spaced repetitions of the list items (only the massed condition was included in the present study). The 30 words were presented auditorily at a rate of 1 word per 1,500 ms, repeated three times in a row. For the purposes of the temporal-contiguity analyses here, we redefined the serial position of each item as its position in the 30-item list

of unique words presented. That is, if a list started "absence, absence, absence, hollow, hollow, hollow . . . ," the word "absence" was assigned Serial Position 1 and the word "hollow" was assigned Serial Position 2. After the presentation of the last item, participants solved math problems of the form $A + B + C = ?$ (where A, B, and C were positive, single-digit integers) until they had correctly answered 15 problems in a row. After completing the self-paced distractor task, which took on average 45 ms, participants recalled the words on the just-studied list in any order during a 90-s recall period.

Bridge (2006) In single sessions, 119 participants performed free recall of 18 lists. Each list was made up of 25 nouns drawn randomly and without replacement from the Toronto Word Pool (Friendly et al., 1982). Words were presented visually for a maximum of 1,100 ms each, with a 200-ms ISI. During each word presentation, the participants were required to indicate whether the word was "concrete" or "abstract" by pressing either the left or the right control keys within the 1,100-ms time limit. Once they made a response, the ISI period was initiated. After the presentation of the last item, participants solved math problems of the form $A + B + C = ?$ (where A, B, and C were positive, single-digit integers) for 30 s, before recalling the words on the just-studied list in any order during a 60-s recall period. Note that 57 trials (never more than 6 from any participant) were excluded due to a combination of mechanical failure and experimenter error.

Sederberg et al. (2006a) Across three separate testing sessions, 48 participants performed free recall of 48 lists. The lists were composed of 15 high-frequency nouns, presented visually for 1,600 ms with a 800- to 1,200-ms blank ISI. After the presentation of the last item, participants solved math problems of the form $A + B + C = ?$ (where A, B, and C were positive, single-digit integers) for 20 s, before recalling the words on the just-studied list in any order during a 45-s recall period. The number of participants reported here is higher than the 35 reported in Sederberg et al. (2006a) because additional data were collected subsequent to the article's publication.

Zaromb et al. (2006), Exp. 1 In single sessions, 100 participants performed free recall of 16 lists, each of which contained 20 common nouns drawn from the Toronto Word Pool (Friendly et al., 1982). The lists were designed such that the first 2 lists were each composed of 20 unique words. The remaining 14 lists each contained up to four items repeated from 1, 2, 4, or 8 lists back, randomly selected from within that list. The words were presented visually for 1,400 ms, followed by a 200-ms ISI. After the presentation of the last item, participants solved math problems of the form $A + B + C = ?$ (where A, B, and C were positive, single-

digit integers) for 16 s, before recalling the words on the just-studied list in any order during a 90-s recall period.

Zaromb et al. (2006), Exp. 2 In single sessions, 42 older and 63 younger participants performed free recall of 14 lists, each of which contained 20 common nouns drawn from a modified version of the Toronto Word Pool (Friendly et al., 1982) that had words with negative connotations removed. The lists were designed such that the first 4 lists were each composed of 20 unique words. Of the remaining 10 lists, 3 contained all new items, and 7 contained six items repeated from 1, 2, and 3 lists back (i.e., two from one list back, two from two lists back, and two from three lists back), randomly selected from within that list. The words were presented visually for 1,400 ms, followed by a 200-ms ISI. After the presentation of the last item, participants solved math problems of the form $A + B + C = ?$ (where A, B, and C were positive, single-digit integers) for 16 s, before recalling the words on the just-studied list in any order during a 90-s recall period.

Howard, Venkatadass, Norman, and Kahana (2007), Control lists In single sessions, 294 participants (1 was excluded from the original study because of experimenter error) performed immediate free recall of 48 lists, each composed of 10 randomly selected nouns from the Toronto Word Pool (Friendly et al., 1982). Half of these lists were in the experimental condition, in which items were repeated within a list, whereas the half in the control condition contained no repeated item presentations. Only the control lists have been used here. Each item was presented both visually and auditorily for a maximum of 1,200 ms, with a 500-ms ISI. Participants were required to indicate whether the word was "concrete" or "abstract" by pressing either the left or the right control key within the 1,200-ms time limit, after which the ISI period was initiated. After the last item, participants began recalling the words on the just-studied list in any order during a 30-s recall period.

Polyn et al. (2009) Across two separate testing sessions, 45 participants performed immediate free recall of 34 total lists (17 per session). Each list was composed of 24 items selected from the word association space norms (Steyvers et al., 2004). For each item, participants were asked to make either a size judgment ("Will this item fit in a shoebox?") or an animacy judgment ("Is this item living or nonliving?"). Items were presented visually for 3,000 ms, with an 800-ms ISI, and participants indicated their responses during the item presentation via keypresses. After the final item, participants began recalling the words on the just-studied list in any order during a 90-s recall period.

Morton et al. (submitted) Across three separate testing sessions, 38 participants performed immediate free recall of

48 total lists (16 per session). Each list was composed of a series of 24 photographs drawn from three categories: famous people, well-known landmarks, and common objects. For each category, participants were asked to rate on a scale from 1 to 4 how much they liked the celebrity, how much they wanted to visit the landmark, or how often they encountered the object. The photographs were presented visually for 3,500 ms, with an 800-ms ISI, and participants indicated their ratings during the item presentation via keypresses. After the final item presentation, participants began recalling the words on the just-studied list in any order during a 90-s recall period.

Cohen et al. (2010) Across four separate testing sessions, 42 participants performed immediate free recall of 48 total lists (12 per session). Each list was composed of 24 items selected from the word association space norms (Steyvers et al., 2004). For each item, participants were asked to either make a size judgment ("Will this item fit in a shoebox?") or an animacy judgment ("Is this item living or nonliving?"). The items were presented visually for 3,000 ms, with an 800-ms ISI, and participants indicated their responses during the item presentation via keypresses. After the final item, participants began recalling the words on the just-studied list in any order during a 90-s recall period.

Sederberg et al. (2006b) Across three separate testing sessions, 37 participants performed free recall of 48 total lists (16 per session). Each list was generated to ensure that words with varying degrees of semantic relatedness occurred at both adjacent and distant serial positions. Noun pairs from the word pool were divided into four groups of increasing semantic relatedness on the basis of the word association space norms (Steyvers et al., 2004), a computational measure of semantic similarity derived from free-association norms (Nelson, McKinney, Gee, & Janczura, 1998). Two pairs of items from each of the four groups (i.e., 16 items per list) were selected without replacement for each list and arranged such that one pair occurred at adjacent serial positions and the other pair was separated by at least two other items. Each word was presented visually for 1,000 ms, with a 300- to 700-ms blank ISI. After the presentation of the last item, participants solved math problems of the form $A + B + C = ?$ (where A, B, and C were positive, single-digit integers) for 20 s before recalling the words on the just-studied list in any order during a 45-s recall period.
